(Dated: January 6, 2011)

The production of new particles at a hadron collider like the LHC is always accompanied by QCD radiation attributable to the initial state (i.e. ISR). This tends to complicate analyses, so ISR is normally regarded as a nuisance. Nevertheless, we show that ISR can also be valuable, yielding information that can help in the discovery and interpretation of physics beyond the Standard Model. To access this information we will introduce new techniques designed to identify ISR jets on an event-by-event basis, a process we term ISR tagging. As a demonstration of their utility, we will apply these techniques to SUSY di-squark (di-gluino) production to show that they can be used to identify ISR jets in roughly 40% (15%) of the events, with a mistag rate of around 10% (15%). We then show that, through the application of a new method which we will introduce, knowledge of an ISR jet allows us to infer the squark (gluino) mass to within roughly 20% of its true value.

I. INTRODUCTION

Quarks and gluons are always splitting apart and recombining [1]. When they are scattered at high energies this process is interrupted, and the result is that additional quarks and gluons which could not be recombined end up in the final state. This radiation, attributable to the splitting of the incoming states, is termed initial state radiation (ISR).

ISR often complicates analyses. For example, it can overlap with, and thus contaminate, jets formed from the decay of new particles (we will call these *FSR jets*). Furthermore, when ISR emissions yield additional independent jets (i.e. *ISR jets*), sorting out the combinatorics of an event can be even more difficult. These are not irresolvable difficulties, and indeed recently progress has been made toward removing sources of jet contamination [2], mitigating combinatorial difficulties [3], defining new observables less sensitive to contamination [4], and more accurately accounting for the physics of ISR in Monte Carlo simulations [5].

However, ISR – rather than always proving to be an obstacle – can actually be helpful in the study of physics beyond the SM. This has already been demonstrated in several recent studies. In Ref. [6], ISR was shown to make BSM events more prominent by giving pair-produced new-physics states something to recoil against, thus increasing both $\cancel{E}_T$ and H_T . Meanwhile, Ref. [7] took a different approach, calculating the influence of ISR on inclusive variables (which sum over everything measured in the detector) with the aim of inferring the mass scale probed in new-physics events.

ISR's utility lies primarily in the fact that the physics of its production is (approximately) dependent only upon

the mass scale of the event and the states it couples to – independently of any intermediate or final decay products. So while the kinematic quantities measured of FSR jets in BSM processes depend upon some combination of all the masses involved in the process, the kinematics of ISR depend upon *only* the masses of the particles involved in the production process (i.e. not upon those produced subsequently in a cascade/decay) and their couplings to initial state particles.

Here we will make use of this information carried by ISR, with the main new feature of our approach being that rather than treating ISR in an inclusive way, as in Ref. [7], *we will seek to identify a particular jet as attributable to ISR*. We will see that such jets can be identified on an event-by-event basis with a small mistagging probability. We will then show that this sort of technique for tagging ISR jets provides a powerful tool for understanding BSM physics that can be applied to many interesting processes. We focus in particular on a new kinematic method that can be used to evaluate squark and gluino masses.

The outline of this paper is as follows. Sec. II will discuss the sort of techniques one can use to tag ISR jets, Sec. III will discuss one example of what we can learn about BSM physics through the study of ISR jets based solely on kinematics, and Sec. IV will apply these ideas to di-squark and di-gluino production as a demonstration of their feasibility and utility. Finally, Sec. V contains our conclusions.

II. TAGGING AN ISR JET

Tagging an ISR jet requires identifying characteristics that distinguish it from the other jets in an event. Although ISR possesses some general traits that hold true regardless of the process at hand [8], tagging ISR jets solely based on these properties would be challenging, if not impossible. We instead focus on tagging ISR in a

* dkrohn@physics.harvard.edu

† randall@physics.harvard.edu

‡ lianwang@princeton.edu

particular class of interesting processes – the pair production of BSM particles, each of which decays into jets and an invisible particle (i.e. $pp \rightarrow N_f J + 2\chi_1^0 + \text{ISR}$ where $N_f = 2/4$ for di-squark/di-gluino production). Although we will restrict ourselves to these topologies, we expect that ISR jets are also identifiable in other cases and that similar techniques could be developed for more complicated processes. Nonetheless, this will serve as a proof of concept, that we employ later in Sec. IV, in what is already an important application of these ideas to BSM physics.

It turns out that the modest assumption of pair production gives one a significant handle for identifying ISR jets. Suppose one expects to see N_f FSR jets in a BSM event. As long as there's no reason for these to be particularly soft, one can assume that of the $N_f + 1$ hardest jets in the event, N_f are attributable to FSR and one to ISR. As the production process is symmetric, all of the properties governing the production of one FSR jet should hold for the others. Thus, of the $N_f + 1$ hardest jets in the event, we can identify the ISR jet as the one which is in some way distinguished from the others.

The method we prescribe for accomplishing this is to consider the $N_f + 1$ hardest jets in an event and identify a candidate ISR jet (here labeled i) for which at least one of the following conditions is met [9]:

1. The jet's p_T is distinct (i.e. it is harder or softer than the others):

$$\frac{\max(p_{Ti}, p_{Tj})}{\min(p_{Ti}, p_{Tj})} > 2 \quad \forall j \neq i \quad (1)$$

2. The jet is separated from the others in rapidity:

$$|y_i - y_j| > 1.5 \quad \forall j \neq i \quad (2)$$

3. The jet is distinguished by its $m_i/p_{Ti} \equiv \Delta_i$ ratio [10]:

$$\frac{\max(\Delta_i, \Delta_j)}{\min(\Delta_i, \Delta_j)} > 1.5 \quad \forall j \neq i \quad (3)$$

If a jet (again labeled i) is selected by any of the above criteria it should then satisfy *all* of the following:

- The selected jet must not be central: $|y_i| > 1$.
- It must not be too close to the other jets, which are all implicitly FSR jets:

$$|y_i - y_j| > 0.5 \quad \forall j \neq i \quad (4)$$

- These other jets must be reasonably close to each other in p_T :

$$\frac{p_{Tj}}{p_{Tk}} < \rho + \frac{1/2}{1 - \alpha} \quad (5)$$

for $p_{Tj(k)} = \max(\min)\{p_{Tl} | \forall l \neq i\}$, with $\rho = 2(3)$ for $N_f = 2(4)$, and where we have introduced the variable

$$\alpha = \frac{\min(p_{Ti}, \cancel{E}_T)}{\max(p_{Ti}, \cancel{E}_T)} \quad (6)$$

to relax this condition when the ISR is very hard.

- Finally, the implicit FSR jets must be somewhat central: $|y_j| < 2 \quad \forall j \neq i$

If any of the above conditions is not satisfied, the jet being considered is not tagged and other jets are checked to see if they pass any of the distinguishing criteria (Eqs. 1-3).

We note that it is surely possible to improve upon the technique presented above, and that the numerical values we presented have not been thoroughly optimized. Even so, we will see these criteria already work quite well, triggering on 40% (15%) of the events, for $N_f = 2(4)$ topologies, with a small 10% (15%) mistag rate.

III. USES OF AN ISR JET

Once an ISR jet has been identified in an event it can be used in multiple ways to shed light upon the underlying physics that produced it. As the production of ISR is determined by the mass scale probed by the process, the identity of the partons in the initial state, and the relevant parton distribution functions (PDFs), the resulting ISR kinematical distributions will reflect all of these influences [11]. Here though, rather than focus on general properties of the aforementioned distributions, whose calculation would depend upon a careful treatment of QCD, we will instead present a simple new kinematical technique useful in measuring m_{BSM} , the center of mass energy for the two heaviest BSM particles produced in the symmetric processes we are considering. Because hadron colliders tend to produce heavy states close to threshold, a measurement of m_{BSM} is nearly equivalent to a measurement of the new-physics particle's mass: $m_{\text{BSM}} = \sqrt{(p_{\bar{q}/\bar{g}} + p_{q^*/g})^2} \approx 2m_{\bar{q}/\bar{g}}$.

Other kinematic variables are also sensitive in some way to m_{BSM} . Examples include M_{eff} [12], M_{T_2} [13], and their more advanced extensions [14]. Some recent works [15] have also made use of ISR to give their M_{T_2} distributions additional structure. However, these techniques are in general sensitive to all of the masses in the decay chain, or only work for very specific processes (e.g. gluino stansverse mass [14]).

Remarkably, by looking to ISR we can construct a new kinematic measure sensitive only to m_{BSM} , independent of any other assumptions on the spectrum. The basic idea behind this method stems from the observation that any BSM particles produced must be recoiling against ISR in the transverse plane. Boosting the FSR system back along the transverse plane to compensate for the

ISR jet's p_T requires an assumption for the system's center of mass energy, and only when we have assumed the correct value will the boost function properly. Before proceeding, we note that while any BSM particles are, in fact, recoiling against all of the ISR particles (rather than only the leading jet), in practice the ISR jets assume a strong p_T hierarchy and using only the leading jet to apply a boost will serve as a reasonable approximation.

In detail, the method we prescribe to measure m_{BSM} using the ISR jet's kinematics is to:

1. Identify all of the visible FSR jets and boost them along the z direction so that the visible FSR is at rest in the z frame (i.e. the net p_z for FSR jets is zero). That is, each FSR four-vector (here labeled i) is shifted

$$E_i \rightarrow \gamma(E_i + \beta p_{iz}), \quad p_{iz} \rightarrow \gamma(\beta E_i + p_{iz}) \quad (7)$$

where $\beta = -p_z/E$ and $\gamma = 1/\sqrt{1-\beta^2}$, for p_z and E the sum longitudinal momentum and energy taken over all observable particles in the system. This boost is performed because, while ideally the system will be at rest in the z direction before boosting in the transverse plane (step two), this is a configuration we cannot achieve because of uncertainties introduced by missing energy. However, by applying the boost in Eq. (7) we approximate this condition.

2. Boost the system along the direction transverse to the beam, parallel to the transverse momentum of the ISR jet, assuming some system mass M . This means that the projection of each FSR p_T vector along the ISR direction transforms as

$$p_{\bar{T}i} \rightarrow \frac{p_T^{\text{ISR}}}{M} E_i + \sqrt{1 + \left(\frac{p_T^{\text{ISR}}}{M}\right)^2} p_{\bar{T}i} \quad (8)$$

where $p_{\bar{T}i} = \vec{p}_T \cdot \hat{p}_T^{\text{ISR}}$ is the projection of each p_T along the ISR p_T direction.

3. Measure the sum projection of the resulting boosted FSR along the ISR transverse direction, assigning the result a ± 1 depending upon the sign:

$$\sigma = \begin{cases} +1 & \text{if } \sum_i p_{\bar{T}i} > 0 \\ -1 & \text{if } \sum_i p_{\bar{T}i} < 0 \end{cases} \quad (9)$$

4. Finally, the average projection across many events is measured: $\langle \sigma \rangle = \sum_{i=1}^N \sigma_i / N$

When $\langle \sigma \rangle$ is positive there is a net projection along the ISR axis, indicating the assumed mass is too small, while when it is negative, the assumed mass is too large. Examples of the resulting distributions are shown in Fig. 1 for the case of di-squark and di-gluino production.

Before proceeding, we call attention to two choices we made in the analysis that might be improved in a more

TABLE I. ISR tagging efficiencies computed for different choices of spectra. The first four rows are for di-squark production, and the last four are for di-gluino production.

Spectrum		Efficiencies [%]		Type of tag applied [%]		
$m_{\tilde{q}}/m_{\tilde{g}}$	m_{LSP}	Trigger	Mistag	Eq. (1)	Eq. (2)	Eq. (3)
500 GeV	100 GeV	42	15	69	22	9
500 GeV	450 GeV	42	12	52	39	9
1 TeV	100 GeV	41	11	79	14	7
1 TeV	950 GeV	41	9	52	39	9
500 GeV	100 GeV	13	22	48	42	10
500 GeV	400 GeV	15	10	35	58	6
1 TeV	100 GeV	12	25	59	30	11
1 TeV	900 GeV	16	8	37	57	6

careful treatment. The first is in step one, where we boosted the FSR along the z direction to approximate the longitudinal rest frame. While this technique seems to operate reasonably well, it may be possible to better infer the z -boost using beam thrust techniques as suggested in Ref. [16]. We further note that Eq. (9) assigns each event an equal weight when computing $\langle \sigma \rangle$, regardless of the measured imbalance. This choice was made because weighting events by their p_T imbalance ($\sum_i p_{\bar{T}i}$) tends to make $\langle \sigma \rangle$ sensitive to only a few outlier events. Perhaps a better measure exists, but we do not pursue it here.

IV. EXAMPLE: DI-SQUARK & DI-GLUINO PRODUCTION

We now apply the aforementioned techniques to the pair production of squarks and gluinos, letting $\tilde{q} \rightarrow q + \chi_1^0$ and $\tilde{g} \rightarrow q\bar{q} + \chi_1^0$ (via an off-shell squark). To perform this analysis we use **Madgraph v4.4.51** [17] to generate 10^5 -event samples at matrix-element level, assuming a 14 TeV LHC, which are then showered in **Pythia v6.422** [18] and matched using the MLM procedure [19]. Fully showered and hadronized events are then grouped into 0.1×0.1 cells (η, ϕ) cells between $-5 < \eta < 5$, which are clustered in **Fastjet v2.4.2** [20] using the anti- k_T algorithm [21]. Our di-squark samples were clustered using $R = 0.7$, while $R = 0.4$ was used for the busier di-gluino events. Note that, to simplify matters, we have not accounted for the effects of multiple interactions or pileup.

Table I shows the efficiencies found using the tagging procedure of Sec. II. Remarkably, we see that the tagging efficiency (i.e. the percent of events in which an ISR jet is tagged) and the mistag rate (the percent of events in which a jet that has been tagged as ISR was tagged incorrectly) are stable, even when comparing a standard SUSY spectrum with $m_{\text{LSP}} = 100$ GeV to one in which the LSP is nearly degenerate with the supersymmetric particle that decayed into it.

Fig. 1 shows the distribution of $\langle \sigma \rangle$ for the spectra in Table I where we see that the kinematical technique introduced earlier works quite well: $\langle m_{\text{BSM}} \rangle = 1.3$ TeV

for $m_{\tilde{q}}/m_{\tilde{g}} = 500$ GeV and $\langle m_{\text{BSM}} \rangle = 2.5$ TeV for $m_{\tilde{q}}/m_{\tilde{g}} = 1$ TeV, values which are quite close to those measured by the point at which the FSR momentum have been boosted to have no preferred direction ($\langle \sigma \rangle = 0$).

V. CONCLUSION

While ISR is normally regarded as a nuisance, here we have seen that it can instead be useful, allowing for qualitatively new measurements of BSM physics that would be difficult or impossible to otherwise access. In this paper, we have introduced a set of techniques for tagging the ISR created in the pair production of BSM states, each of which decays into jets and an invisible particle. Although the methods we introduced are specific to this sort of process, they can be readily extended to scenarios where BSM physics realizes a more complicated final state topology.

We have applied these techniques to SUSY di-squark (di-gluino) production, where we saw they tagged ISR in roughly 40% (15%) of the events, with a mistag rate of around only 10% (15%). This allowed us to make a

qualitatively new measurement, using a kinematic technique we introduced, of the squark/gluino mass to within roughly 20% of its true value, without making any assumptions on the rest of the SUSY spectrum.

Given the success of this relatively simple procedure, we expect that more elaborate ISR taggers (employing, for example, the information contained in jet substructure) could be constructed for use in other topologies to produce new and complementary measurements of both SM physics and physics beyond the Standard Model.

 - [8] E.g. it is not very correlated in rapidity with FSR jets.
 - [9] It is possible, although rare, for more than one jet to pass Eqs.(1-3). If this happens we rank the tagging criteria by the order in which they are listed, e.g. accepting a jet which passes Eq. (1) over one which passes only Eq. (3), etc. If more than one jet pass the same tagging criteria, we take as our candidate for Eq. (1) the hardest jet, and for Eq. (3) the jet with the largest Δ . If more than one jet pass Eq. (2), none are accepted.
 - [10] We note that Δ is sensitive to higher order emissions, in contrast to the criteria of Eqs.(1-2). Further work along this line, particularly in employing jet substructure (see Ref. [22] for a review), could potentially improve upon the methods presented herein.
 - [11] We will pursue these ideas in a followup paper.

FIG. 1. The average sign of the FSR projection along the transverse ISR direction for, proceeding left to right, di-squark production using $m_{\tilde{q}} = 500$ GeV, $m_{\tilde{q}} = 1$ TeV, and then di-gluino production with $m_{\tilde{g}} = 500$ GeV, $m_{\tilde{g}} = 1$ TeV, with the LSP mass indicated in the legends. The position at which the points intersect $\langle\sigma\rangle = 0$ is what we would identify as m_{BSM} , i.e. it where the FSR momenta are balanced because the boost is ‘correct’. We see that it is in general close to $2m_{\tilde{q}/\tilde{g}}$. Note that the errors indicated are just the statistical errors associated with our Monte Carlo sample sizes.
